

# Seeking an Optimal Approach for Computer-aided Pulmonary Embolism Detection

Pulmonary embolism (PE) represents a thrombus (“blood clot”), usually originating from a lower extremity vein, that travels to the blood vessels in the lung, causing vascular obstruction, and in some patients, death. We present a comprehensive analysis of competing deep learning methods applicable to PE diagnosis using CT pulmonary angiography at both the slice and exam levels.

**Contributions:** Extensive experiments that compare architectures, model initializations, and learning paradigms; an optimal approach for PE detection, achieving an AUC gain of 0.2% and 1.05% at the slice and exam levels, respectively, compared with the state-of-the-art method.

## Self-supervised pre-training overtakes (fully) supervised pre-training

## Bidirectional GRU marginally outperforms attention-based deep MIL at the exam level
